classic example [29]. Next, multiple central processors were connected to a common memory to provide more power for compute-bound applications [33]. For certain of these applications, more exotic multiprocessor architectures such as Illiao IV were introduced [5].

recures sure as mine 1 were introduced [5].

More recently minicomputers have been connected in multiprocessor configurations for economy, reliability, and increased system modularity [24, 36]. The trend has been toward decentralization for reliability, loosely coupled multiprocessor systems depend less on stared central memory and more on thin wires for inspared central memory and more on thin wires for inspared central memory and more on thin wires for interprocess communication with increased component isolation [18, 26]. With the continued thinning of interprocessor communication for reliability and the development of distributable applications, multiprocessing is gradually approaching a local form of distributed computing.

# 1.3 Local Computer Networking

Ethernet shares many objectives with other local networks such as Mitre's Mitrix, Bell Telephone Laboranory's Spider, and U.C. Irvine's Distributed Computing System (DCS) [12, 13, 14, 35]. Prototypes of all four local networking schemes operate at bit rates between one and three megabits per second. Mitrix and Spider width allocation, while DCS and Ethernet use distributed control. Spider and DCS use a ring communication path, Mitrix uses off-the-shelf CATV technology to implement two one-way busses, and our experimental Ethernet uses a branching two-way passive bus. Differences among these systems are due to differences among their intrade-offs were made, and differences of opinion among researchers.

Before going into a detailed description of Ethernet, we offer the following overview (see Figure 1).

## 2. System Summary

Ethernet is a system for local communication among computing stations. Our experimental Ethernet uses tapped coaxial cables to carry variable length digital data packets among, for example, personal minicomputers, printing facilities, large file storage devices, magnetic tape backup stations, larger central computers, and longer-haul communication equipment.

The shared communication facility, a branching Ether, is passive. A station's Ethernet interface connects bit-scrially through an interface cable to a transceiver which in turn taps into the passing Ether. A packet is broadcast onto the Ether, is heard by all stations, and is copied from the Ether by destinations which select it according to the packet's leading address bits. This is broadcast packet switching and should be bits. This is broadcast packet switching and should be in which routing is performed by intermediate process-

ing elements. To handle the demands of growth, an Ethernet can be extended using packet repeaters for signal regeneration, packet filters for traffic localization,

completion without interference. Ethernet controllers and packet gateways for internetwork address extension. to any which may already be in progress. Once started, if interference with other packets is detected, a transmission is aborted and rescheduled by its source mission, a packet is heard by all stations and will run to sion intervals to avoid repeated collisions. The mean of tion of collision history to keep Ether utilization near Control is completely distributed among stations, cal arbitration. Transmissions initiated by a station destation. After a certain period of interference-free transin colliding stations each generate random retransmisa packet's retransmission intervals is adjusted as a funcwith packet transmissions coordinated through statistithe optimum with changing network load. Ē

Even when transmitted without source-detected interference, a packet may still not reach its destination without error; thus, packets are delivered only with high probability. Stations requiring a residual error rate lower than that provided by the bare Ethernet packet transport mechanism must follow mutually agreed upon packet protocols.

## 3. Design Principles

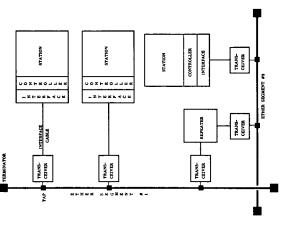

Our object is to design a communication system which can grow smoothly to accommodate several buildings full of personal computers and the facilities needed for their support.

Like the computing stations to be connected, the communication system must be inexpensive. We choose to distribute control of the communications facility among the communicating computers to eliminate the reliability problems of an active central controller, to avoid creating a bottleneck in a system rich in parallel, ism, and to reduce the fixed costs which make small systems uneconomical.

Ethernet design started with the basic idea of packet collision and retransmission developed in the Aloha Network [1]. We expected that, like the Aloha Network, Ethernets would earry bursty traffic so that conventional synchronous time-division multiplexing (STDM) would be inefficient [1, 2, 21, 26]. We saw promise in the Aloha approach to distributed control of radio channel multiplexing and hoped that it could be applied effectively with media suited to local computer communication. With several innovations of our own, the promise is realized.

Ethernet is named for the historical *luminiferous* ether through which electromagnetic radiations were once alleged to propagate. Like an Aloha radio transmitter, an Ethernet transmitter broadcasts completely-addressed transmitter-synchronous bit sequences called packets onto the Ether and hopes that they are heard by

Fig. 1. A two-segment Ethernet.

the intended receivers. The Ether is a logically passive medium for the propagation of digital signals and can be constructed using any number of media including coaxial cables, twisted pairs, and optical fibers.

## 1 Topology

We cannot afford the redundant connections and dynamic routing of store-and-forward packet switching to assure reliable communication, so we choose to achieve reliability through simplicity. We choose to make the shared communication facility passive so that the failure of an active element will tend to affect the communications of only a single station. The layout and changing needs of office and laboratory buildings leads us to pick a network topology with the potential for convenient incremental extention and reconfiguration with minimal service disruption.

The topology of the Ethernet is that of an unrooted tree. It is a *tree* so that the Ether can branch at the entrance to a building's corridor, yet avoid multipath interference. There must be only one path through the Ether between any source and destination; if more than one path were to exist, a transmission would interfer with itself, repeatedly arriving at its intended destination who may graveled by paths of different length. The Ether is *unrooted* because it can be extended from any of its points in any direction. Any station wishing to join

an Ethernet taps into the Ether at the nearest convenient

Looking at the relationship of interconnection and control, we see that Ethernet is the dual of a star network. Rather than distributed interconnection through many separate links and central control in a switching node, as in a star network, the Ethernet has central interconnection through the Ether and distributed control among its stations.

morphic as saudona Network, which is a star network Unlike an Aloha Network, which an outgoing broadcast channel and an incoming multi-access channel, an Ethernet supports many-to-many communication with a single broadcast multi-access channel.

### Control

Sharing of the Ether is controlled in such a way that it is not only possible but probable that two or more stations will attempt to transmit a packet at roughly the same time. Packets which overlap in time on the Ether are said to collide; they interfere so as to be unrecognizable by a receiver. A station recovers from a detected collision by abandoning the attempt and retransmitting the packet after some dynamically chosen random time period. Arbitration of conflicting transmission demands is both distributed and statistical.

When the Ether is largely unused, a station transmits its packets at will, the packets are received without error, and all is well. As more stations begin to transmit, the rate of packet interference increases. Ethernet controllers in each station are built to adjust the mean retransmission interval in proportion to the frequency of collisones, sharing of the Ether among competing station-station transmissions is thereby Kept near the optimum [20, 21].

A degree of cooperation among the stations is required to share the Ether quired by. In demanding applications certain stations might usefully take transmission priority through some systematic violation of equity rules. A station could usurp the Ether by not adjusting its retransmission interval with increasing traffic or by sending very large packets. Both practices are now prohibited by low-level software in each station.

## 3.3 Addressing

Each packet has a source and destination, both of which are identified in the packet's header. A packet placed on the Ether eventually propagates to all stations. Any station can copy a packet from the Ether into its local memory, but normally only an active destination station matching its address in the packet's header will do so as the packet passes. By convention, a zero destination address is a wildcard and matches all addresses; a packet with a destination of zero is called a broadcast packet.

## 3.4 Reliability

An Ethernet is probabilistic. Packets may be lost due to interference with other packets, impulse noise on the

Ether, an inactive receiver at a packet's intended destination, or purposeful discard. Protocols used to communicate through an Ethernet must assume that packets will be received correctly at intended destinations only with high probability.

An Ethernet gives its best efforts to transmit packets successfully, but it is the responsibility of processes in the source and destination stations to take the precautions necessary to assure reliable communication of the quality sion and high reliability averaged over many packets cation from the packet transport mechanism allows us to ness and dangers of promising "error-free" communication, we refrain from guaranteeing reliable delivery tailor reliability to the application and to place error rein a hierarchy of networks through which packets must they themselves desire [18, 21]. Recognizing the costliof any single packet to get both economy of transmis-Removing the responsibility for reliable communicovery where it will do the most good. This policy becomes more important as Ethernets are interconnected travel farther and suffer greater risks.

## 3.5 Mechanisms

A station connects to the Ether with a tap and a transceiver. A tap is a device for physically connecting to the Ether while disturbing its transmission characteristics as little as possible. The design of the transceiver must be an exercise in paranoia. Precautions must be taken to insure that likely failures in the transceiver or station do not result in pollution of the Ether. In particular, removing power from the transceiver should eause it to disconnect from the Ether.

Five mechanisms are provided in our experimental Ethernet for reducing the probability and cost of losing a packet. These are (1) carrier detection, (2) interference detection, (3) packet error detection, (4) truncated packet filtering, and (5) collision consensus enforcement.

bits on a magnetic tape), which guarantees that there is the Ether by a station, they are phase encoded (like 3.5.1 Carrier detection. As a packet's bits are placed at least one transition on the Ether during each bit time. The passing of a packet on the Ether can therefore be detected by listening for its transitions. To use a radio analogy, we speak of the presence of carrier as a packet rier of a passing packet, it can delay sending one of its passes a transceiver. Because a station can sense the carown until the detected packet passes safely. The Aloha Network does not have carrier detection and consequently suffers a substantially higher collision rate. Without carrier detection, efficient use of the Ether would decrease with increasing packet length. In Section below, we show that with carrier detection, Ether efficiency increases with increasing packet length. 60

With carrier detection we are able to implement deference: no station will start transmitting while hearing carrier. With deference comes acquisition: once a packet transmission has been in progress for an Ether end-to-

end propagation time, all stations are hearing carrier and are deferring; the Ether has been acquired and the transmission will complete without an interfering colli-

With carrier detection, collisions should occur only when two or more stations find the Ether silent and begin transmitting simultaneously: within an Ether end-to-propagation time. This will almost always happen immediately after a packet transmission during which two or more stations were deferring. Because stations do not now randomize after deferring, when the transmission terminates, the waiting stations pile on together, collide, randomize, and retransmit.

3.5.2 Interference detection. Each transceiver has an interference detector. Interference is indicated when the transceiver notices a difference between the value of the bit it is receiving from the Ether and the value of the bit is attempting to transmit.

Interference detection has three advantages. First, a station detecting a collision knows that its packet has bead admaged. The packet can be scheduled for reternamission immediately, avoiding a long acknowledgment timeout. Second, interference periods on the Ether are limited to a maximum of one round ripp time. Colliding packets in the Aloha Network run to completion, but the truncated packets resulting from Ethernet collisions waste only a small fraction of a packet time on the Ether. Third, the frequency of detected interference is used to estimate Ether traffic for adjusting retransmission intervals and optimizing channel efficiency.

3.5.3 Packet error detection. As a packet is placed on the Ether, a checksum is computed and appended. As the packet is read from the Ether, the checksum is recomputed. Packets which do not carry a consistent checksum are discarded. In this way transmission errors, impulse noise errors, and errors due to undetected interference are caught at a packet's destination.

3.5.4 Truncated packet filtering. Interference detection and deference cause most collisions to result in truncated packets of only a few bits; colliding stations detect interference and abort transmission within an Ether round trip time. To reduce the processing load that the rejection of such obviously damaged packets would place on listening station software, truncated packets are filtered out in hardware.

3.5.5 Collision consensus enforcement. When a station determines that its transmission is experiencing interference, it momentarily jams the Ether to insure that all other participants in the collision will detect interference and, because of deference, will be forced to about. Without this collision consensus enforcement mechanism, it is possible that the transmitting station which would otherwise be the last to detect a collision might not do so as the other interfering transmissions successively abort and stop interfering. Although the packet may look good to that last transmitter, different path lengths

between the colliding transmitters and the intended receiver will cause the packet to arrive damaged.

## 4. Implementation

Our choices of 1 kilometer, 3 megabits per second, and 256 stations for the parameters of an experimental Ethernet were based on characteristics of the locally distributed computer communication environment and our assessments of what would be marginally achievable; they were certainly not hard restrictions essential to the Ethernet concept.

We expect that a reasonable maximum network size would be on the order of 1 kilometer of cable. We used this working number to choose among Ethers of varying signal attenuation and to design transceivers with appropriate power and sensitivity.

The dominant station on our experimental Ethernet is a mincomputer for which 3 megabits per second is a convenient data transfer rate. By keeping the peak rate well below that of the computer's part to main memory, we reduce the need for expensive special-purpose packet buffering in our Ethernet interfaces. By keeping the peak rate as high as is convenient, we provide for larger numbers of stations and more ambitious multiprocessing communications applications.

To expedite low-level packet handling among 256 stations, we allocate the first 8-bit byte of the packet to be the destination address field and the second byte to be the source address field (see Figure 2). 256 is a number small enough to allow each station to get an adequate share of the available bandwidth and approaches the limit of what we can achieve with current techniques for tapping cables. 256 is only a convenient number for the lowest level of protocol; higher levels can accomodate extended address spaces with additional fields inside the packet and software to interpret them.

Our experimental Ethernet implementation has four major parts: the Ether, transceivers, interfaces, and controllers (see Figure 1).

### 4.1 Ether

We chose to implement our experimental Ether using low-loss coaxial cable with off-the-shelf CATV taps and connectors. It is possible to mix Ethers on a single Ethernet; we use a smaller-diameter coax for convenient connection within station clusters and a larger-diameter coax for low-loss runs between clusters. The cost of coaxial cable Ether is insignificant relative to the cost of the distributed computing systems supported by Ethernet.

## 4.2 Transceivers

Our experimental transceivers can drive a kilometer of coaxial cable Ether tapped by 256 stations transmitting at 3 megabits per second. The transceivers can endure (i.e. vork after) sustained direct shorting, im-

proper termination of the Ether, and simultaneous drive by all 256 stations; they can tolerate (i.e. work during) ground differentials and everyday electrical noise, from typewriters or electric drills, encountered when stations are separated by as much as a kilometer.

An Ethernet transceiver attaches directly to the Ether which passes by in the ceiling or under the floor. It is powered and controlled through five twisted pairs in an interface cable carrying transmit data, receive data, interference detect, and power supply voltages. When unpowered, the transceiver disconnects itself electrically from the Ether. Here is where our fight for reliability is won or lost; a broken transceiver can, but should not, bring down an entire Ethernet. A watchdog timer circuit in each transceiver attempts to prevent pollution of the Ether by shutting down the output stage if it acts suspiciously. For transceiver simplicity we use the Ether's base frequency band, but an Ethernet could be built to use any suitably sized band of a frequency division multiplexed Ether.

Even though our experimental transceivers are very simple and can tolerate only limited signal attenuation, they have proven quite adequate and reliable. A more sophisticated transceiver design might permit passive branching of the Ether and wider station separation.

## 4.3 Interface

An Ethernet interface scrializes and deserializes the parallel data used by its station. There are a number of different stations on our Ethernet; an interface must be built for each kind.

Each interface is equipped with the hardware necessary to compute a 16-bit cyclic redundancy checksum (CRC) on serial data as it is transmitted and received. This checksum protects only against errors in the Ether and specifically not against errors in the parallel portions of the interface hardware or station. Higher-level software checksums are recommended for applications in which a higher degree of reliability is required.

A transmitting interface uses a packet buffer address and word count to serialize and phase encode a variable number of 16-bit words which are taken from the station's memory and passed to the transceiver, preceded by a start bit (called SYNC in Figure 2) and followed by the CRC. A receiving interface uses the appearance of carrier to detect the start of a packet and uses the SYNC bit to acquire bit phase. As long as carrier stays on, the interface decodes and descrializes the incoming bit stream depositing 16-bit words in a packet buffer in the station's main memory. When carrier goes away, the interface checks that an integral number of 16-bit words has been received and that the CRC is correct. The last word received is assumed to be the CRC and is not copied nito the packet buffer.

These interfaces ordinarily include hardware for accepting only those packets with appropriate addresses in their headers. Hardware address filtering helps a station avoid burdensome software packet processing when

Fig. 2. Ethernet packet layout.

ADDRESS

the Ether is very busy carrying traffic intended for other

## 4.4 Controller

An Ethernet controller is the station-specific lowlevel firmware or software for getting packets onto and out of the Ether. When a source-detected collision occurs, it is the source controller's responsibility to generate a new random retransmission interval based on the updated collision count. We have studied a number of algorithms for controlling retransmission rates in stations to maintain Ether efficiency [20, 22]. The most practical of these algorithms estimate traffic load using recent collision history.

Retransmission intervals are multiples of a slot, the maximum time between starting a transmission and detection at call as collision, one end-to-end round trip delay. An Ethernet controller begins transmission of each nw packet with a mean retransmission interval of one slot. Each time a transmission attempt ends in collision, the controller delays for an interval of random length with a mean twice that of the previous interval, defers to any passing packet, and then attempts retransmission. This hearistic approximates an algorithm we have called Binary Exponential Backoff (see Figure 3) [22].

When the network is unloaded and collisions are rare, the mean seldom departs from one and retransmissions are prompt. As the traffic load increases, more collisions are experienced, a backlog of packets builds up in the stations, retransmission intervals increase, and retransmission traffic backs off to sustain channel efficiency.

## 5. Growth

## 5.1 Signal Cover

One can expand an Ethernet just so far by adding transceivers and Ether. At some point, the transceivers and Ether and Ether as more point, the transceivers and Ether will be unable to carry the required signals. The signal cover can be extended with a simple unbuffered packet repeater. I. tour experimental Ethernet, where because of transceiver simplicity the Ether cannot be branched passively, a simple repeater may join any number of Ether segments to enrich the topology while standing the signal cover.

We operate an experimental two-segment packet repeater, but hope to avoid relying on them. In branching

the Ether and extending its signal cover, there is a tradeoff between using sophisticated transceivers and using repeaters. With increased power and sensitivity, transceivers become more expensive and less reliable. The introduction of repeaters into an Ethernet makes the centrally interconnecting Ether active. The failure of a transceiver will sever the communications of its owner; the failure of a repeater partitions the Ether severing many communications.

## 5.2 Traffic Cover

One can expand an Ethernet just so far by adding Ether and packet repeaters. At some point the Ether will be so busy that additional stations will just divide more finely the already inadequate bandwidth. The traffic cover can be extended with an unbuffered traffic-filtering repeater or packet filter, which passes packets from one Ether segment to another only if the destination station is located on the new segment. A packet filter also extends the signal cover.

## Address Cover

One can expand an Ethernet just so far by adding Ether, repeaters, and traffic filters. At some point there will be too many stations to be addressed with the Etherner's 8-bit addresses. The address cover can be extended with packet gateways and the software addressing conventions they implement [7]. Addresses can be expanded in two directions: down into the station by adding fields to identify destination ports or processes within a station, and up into the internetwork by adding fields to identify destination stations on remote networks. A gateway also extends the traffic and signal covers.

There can be only one repeater or packet filter connecting two Ether segments; a packet repeated onto a segment by multiple repeaters would interfere with itself. However, there is no limit to the number of gateways connecting two segments; a gateway only repeats packets addressed to itself as an intermediary. Failure of the single repeater connecting two segments partitions the network; failure of a gateway need not partition the net it there are paths through other gateways between the segments.

## Performance

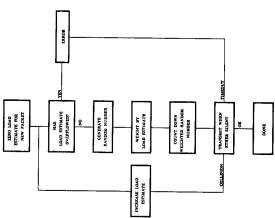

We present here a simple set of formulas with which to characterize the performance expected of an Ethernet when it is heavily loaded. More elaborate analyses and several detailed simulations have been done, but the following simple model has proven very useful in understanding the Ethernet's distributed contention scheme, even when it is loaded beyond expectations [1, 20, 21, 22, 23, 27].

We develop a simple model of the performance of a loaded Ethernet by examining alternating Ether time periods. The first, called a transmission interval, is that

during which the Ether has been acquired for a success ful packet transmission. The second, called a contention interpret, is that composed of the retransmission slots of Section 4.4, during which stations attempt to acquire control of the Ether. Because the model's Ethernets are loaded and because stations defer to passing packets before starting transmission, the slots are synchronized by the tail of the preceding acquisition interval. A slot will be empty when no station chooses to attempt transmission in it and it will contain a collision if more than one station attempts to transmit. When a slot contains only one attempted transmission, then the Ether has even acquired for the duration of a packet, the conten-

tion interval ends, and a transmission interval begins. Let P be the number of bits in an Ethernet packer. Let C be the peak capacity in bits per second, carried on the Ether. Let T be the time in seconds of a slot, the number of seconds it takes to detect a collision after starting a transmission. Let us assume that there are Q stations continuously queued to transmit a packet; either the acquiring station has a new packet immediately after a successful acquisition or another station comes ready. Note that Q also happens to give the total offered load on the network which for this analysis is always 10 or greater. We assume that a queued station at lempts to transmit in the current slot with probability 1/Q, or delays with probability 1-(1/Q); this is known

Fig. 3. Collision control algorithm.

to be the optimum statistical decision rule, approximated in Ethernet stations by means of our load-estimating retransmission control algorithms [20, 21].

## 6.1 Acquisition Probability

We now compute A, the probability that exactly one station attempts a transmission in a slot and therefore acquires the Ether. A is  $Q_*(1/Q)_*(1-(1/Q))_**$  (Q-1); there are Q ways in which one station can choose to transmit (with probability (1/Q)) while Q-1 stations choose to wait (with probability 1-(1/Q)). Simplifying,

$$A = (1 - (1/Q))^{(q-1)}.$$

## 6.2 Waiting Time

We now compute W, the mean number of slots of waiting in a contention interval before a successful acquisition of the Ether by a station's transmission. The probability of waiting no time at all is just A, the probability that one and only one station chooses to transmit in the first slot following a transmission. The probability of waiting I slot is A\*(1-A); the probability of waiting is A\*(1-A); the probability of waiting is A\*(1-A). The mean of this geometric distribution is

## W = (1 - A)/A

## 6.3 Efficiency

We now compute E, that fraction of time the Ether is carrying good packets, the efficiency. The Ether's time is divided between transmission intervals and contention intervals. A packet transmission takes P/C seconds. The mean time to acquisition is W\*T. Therefore, by our simple model,

$$E = (P/C)/((P/C) + (W*T)).$$

Table I presents representative performance figures (i.e. *E*) for our experimental Ethernet with the indicated packet sizes and number of continuously queued stations. The efficiency figures given do not account for inevitable reductions due to headers and control packets nor for losses due to imprecise control of the retransmission parameter 1/Q; the former is straightforwardly proto-col-dependent and the latter requires analysis beyond the scope of this paper. Again, we feel that all of the Ethernets in the table are overloaded; normally loaded Ethernets will usually have a *Q* much less than I and exhibit behavior not covered by this model.

control to the coverted by this model.

For our calculations we use a Cof 3 megabits per second and a Tof 16 microseconds. The slot duration T must be long enough to allow a collision to be detected or at least twice the Ether's round trip time. We limit in software the maximum length of our packets to be near 4000 bits to keep the latency of network access down and to permit efficient use of station packet buffer storage.

io permit efficient use of station packet buffer storage.
For packets whose size is above 4000 bits, the efficiency of our experimental Ethernet stays well above 95

user's peril at either end; the sender may put all I's (an The software checksum word is used to lower the probability of an undetected error. It serves not only as but also for protection against failures in parallel data add and cycle over the entire packet, including header and content data. The checksum can be ignored at the impossible value) into the checksum word to indicate a backup for the experimental Ethernet's serial hardware 16-bit cyclic redundancy checksum (in Figure 2), paths within stations which are not checked by the CRC. The checksum used by the EFTP is a 1's complement to the receiver that no checksum was computed.

7.2.1 Data transfer. The 16-bit words of a file are carried from sending station to receiving station in data packets consecutively numbered from 0. Each data packet is retransmitted periodically by the sender until an ack packet with a matching sequence number is returned from the receiver. The receiver ignores all damaged packets, packets from a station other than the sender, and packets whose sequence number does not match either the expected one or the one preceding. When a packet has the expected sequence number, the packet is acked, its data is accepted as part of the file, and the sequence number is incremented. When a packet arrives with a sequence number one less than that expected, it is acknowledged and discarded; the presumption is that its ack was lost and needs retransmission

then dallys for some reasonably long period of time (10 transmits an echoing endreply and is free to go off with the assurance that the file has been transferred success-7.2.2 End. When all the data has been transmitted, an end packet is sent with the next consecutive sequence number and than the sender waits for a matching endreply. Having accepted an end packet in sequence, the data receiver responds with a matching endreply and seconds). Upon getting the endreply, the sending station fully. The dallying receiver then gets the echoed endreply and it too goes off assured.

Fig. 4. EFTP packet layout.

2 intended to make it practically certain that the sender and receiver of a file will agree on whether the file has data sender simply retransmits it as it would any packet with an overdue acknowledgement. If the endreply from the data receiver is lost, the data sender will time out in the same way and retransmit the end packet which will in turn be acknowledged by the dallying receiver. If the convenienced having to wait for it, but when it has timed out, the receiver can nevertheless be assured of successful transfer of the file because the end packet has been transmitted correctly. If the end packet is lost, the echoed endreply is lost, the dallying receiver will be in-The comparatively complex end-dally sequence been received.

At any time during all of this, either side is free to decide communication has failed and just give up; it is considered polite to send an abort packet to end the communication promptly in the event of, say, a userinitiated abort or a file system error.

in a single network and specifically not from process to control. If data arrives at a receiver unable to accept it ally. There is no way for a receiver to quench the flow of 7.2.3 EFTP shortcomings. The EFTP has been very useful, but its shortcomings are many. First, the protocol provides only for file transfer from station to station process within stations either on the same network or through a gateway. Second, process rendezvous is degenerate in that there are no mechanisms for finding ple users by a single server. Third, there is no real flow into its buffers, the data can simply be thrown away with Fourth, data is transmitted in integral numbers of 16-bit processes by name or for convenient handling of multicomplete assurance that it will be retransmitted eventusuch wasted transmissions or to expedite retransmission.

either terribly restrictive or demands some nested file transfer formats internal to its data words. And fifth, words belonging to unnamed files and thus the EFTP is functional generality is lost because the receiver is also the listener and server

## 8. Conclusion

was well placed. By keeping the shared components of tion and maintenance of our experimental Ethernet has been more than satisfactory. The flexibility of station interconnection provided by broadcast packet switching Our experience with an operating Ethernet leads us the communication system to a minimum and passive, to conclude that our emphasis on distributed control we have achieved a very high level of reliability. Installa has encouraged the development of numerous computer networking and multiprocessing applications.

Lampson, John F. Shoch, and Charles P. Thacker, have Acknowledgments. Our colleagues at the Xerox Palo contributed in many ways to the evolution of Ethernet Alto Research Center, especially Tat C. Lam, Butler W. ideas and to the construction of the experimental system without which such ideas would be just so much speculation

## Computer Architecture? Are You Interested in

pupers on the subject of machine organization or architecture. Of the some 120 odd papers and panels at ACM 70, exactly one (Design Principles of Large Scale Acresque Data Processing, Handling and Dissemination Systems by Eugene Levin) falls in this category. Of the 52 papers in the Journal for 1899 a paper on the "Organization of Large Scule Fourier Poresessors" by Marshall Pases describes a special purpose computer. Of the 155 papers and algorithms in the Communications for 1989, there are four papers which might be considered to be in this field (those by Ernst Ulrich, "Exclusive Simulation of Activity in Bigital Networks"; Niklaus Wirth, "On Multirogramming, Manchine Coding, and Computer Organization"; Herbert Baskin et al., "A Modular Computer Pregrantation"; Herbert Baskin et al., "A Modular Computer System"; and Jack Rosenfeld, "A Case Study in Programming for Parallel-Processors"). In glancing over recent publications of the ACM, I was struck by the dearth of

Thus a total of 6 out of some 330 publications of the Assuriation for Computing Machinery bear on the subject of the design or organization of machinery for computing. Apparently the ACM establishment believes, with many others, that vonNeumann actually did come down the side of Mt. Sinai with two clay tablets under his arm.

If there are others among your read-ers who harbor some doubts about this theory and world be interested in start-ing a SIC on Computer Architecture, I would be interested in hearing from them.

Computer Science Pragram University of Massachusetts Amherst, MA 01002 CAXTON C. FOSTER

little unfair to imply that ACM consciously rejects supporting publications
or other activity relevant to computer
architecture. ACM is, as with any sociely, a reflection of the interests of its
members, and there are unfortunately
always areas relevant to computing not
advantage areas relevant to computing not
advantage areas relevant to computing not
advantage at a lack of such interest. The Communications, in particular, has no such
discrimination policy and would indeed
communes architecture. [Editor's Comment. I believe it is a little unfair to imply that ACM concomputer architecture, design and per-formance; these should be submitted to he Computer Systems Department.-

1970, Mr. Caxton C. Foster questions the fact that "von Neumann In Communications, September,
